Theory of ac-Stark splitting in core-resonant Auger decay under strong x-ray fields

School of Physical Sciences, Dublin City University and NCPTL, Dublin 9, Ireland

In this work we report the modification of the normal Auger line shape under the action of an intense x-ray radiation. Under strong Rabi-type coupling of the core, the Auger line profile develops into a doublet structure with an energy separation mainly determined by the relative strength of the Rabi coupling. In addition, we find that the charge resolved ion yields can be controlled by judicious choice of the x-ray frequency.

INTRODUCTION

The interaction of an atomic system with a radiation field in the regime of x-rays will lead to its ionization. The most dominant process will be, first, the ejection of an inner-shell electron (photo-electron) with the absorption of a photon followed either by an intra-atomic Auger and/or a fluorescence transition. For relatively light atomic systems, the dominant decay channel of the single-hole singly-charged system is through an (radiationless) Auger transition, designated as 'normal Auger' which is a manifestation of electron-electron interaction. One variation on this scenario is to promote an inner-shell electron to an excited bound state, often denoted as Resonant Auger State (RAS), which can decay either through an Auger transition or by the emission of an x-ray photon. This process was first reported by Brown [1] and since then a large number of investigations have taken place (see for example [2] and references there in).

Under excitation by the strong radiation fields, now available, from Free Electron Laser (FEL) sources [3–7], the situation becomes considerably different. Relevant studies in the context of strong laser fields have been reported quite early [8] and in response to recent developments in the x-ray wavelength regime a number of theoretical and experimental works have already appeared [7, 10–13]. In the simplest situation, Rohringer and Santra in Ref. [10] have studied the single-photon excitation of a neon K-shell electron to a RAS by an x-ray field and a multipeak Auger Electron Spectrum (AES) is obtained for the fields they considered. In this work, we examine the AES and the ionic yields in the case where a normal Auger process takes place (as opposed to the RAS process) which involves photoionization of the neutral from the K-shell, followed by an Auger decay of the singly charged hole-system to the doubly charged ion. We demonstrate the emergence of ac-Stark splitting (also known as Autler-Townes splitting [14]) of the Auger resonance, resulting from strong Rabi-coupling of the apposite states in the resulting Ne^{+2} ion. In contrast to RAS line-shape modification [10], the unusual phenomenon here is that the ac-Stark splitting is manifested in the kinetic spectrum of the Auger electron while strong Rabi-coupling occurs to one of the K-shell electrons of the doubly-charged ion. This effect requires an explanation on the basis of a two-electron representation of the Auger-electron ejection, instead of an ambiguous one-electron picture implied by the Rabi-type oscillation of an inner-electron. A detailed study of the two-electron representation, in a different context and formalism but similar physical background, can be found in Ref. [15].

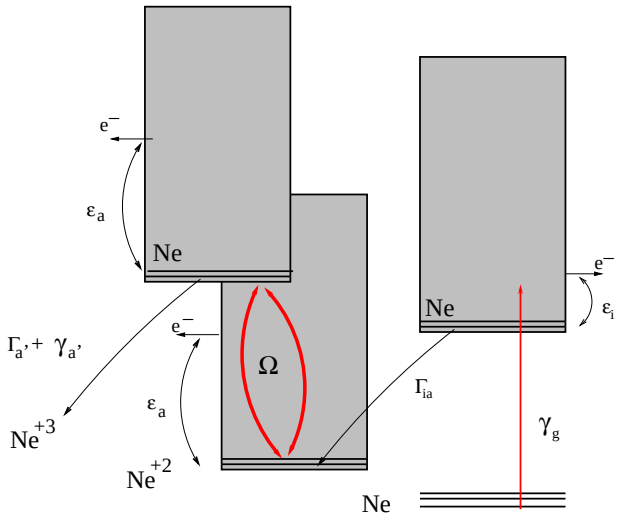

Figure 1. (Color online) Schematic figure of the dominant channels involved in the interaction of neon with an x-ray field of frequency ca. 908.06 eV, chosen to match the $Ne^{+2}(1s^{-1} - 3p)$ transition energy.

We have chosen as the target of our study neutral neon in it's ground state $|G\rangle = |\mathrm{Ne}(1s^2 2s^2 2p^6,\ ^1S_0)\rangle$ and consider radiation with a photon energy of approximately $\omega = 908$ eV (see Fig. 1). The ionization potential for the creation of a K-shell hole $|i\rangle = |\mathrm{Ne}^+(1s2s^2 2p^6,\ ^1P)\rangle$ is $E^{(i)} = 870$ eV. Note that all the energies of the neon states are given relative to the neutral neon ground state. Thus, the x-ray radiation will eject a K-shell photoelectron with a kinetic energy of ca. $\varepsilon_i = 38$ eV. Ionization from the outer shells is also possible but with much lower probability [16]. The generated K-shell hole Ne^+ will decay, by filling the $1s$ vacancy, predominantly to the doubly charged neon state $|a\rangle = |\mathrm{Ne}^{+2}(1s^2 2s^2 2p^4,$

$^1D_2)\rangle$ with energy $E^{(a)} = 65.35$ eV, and Auger decay width $\Gamma_{ia} = 0.27$ eV [16]. In addition, the Ne^+ ion with one K-shell hole can also decay through fluorescence by emitting x-ray radiation [16]. This channel is about 55 times weaker than the Auger decay rate. Let's designate the sum of all decay channels of the $|i\rangle$ state as Γ_i. Normally, this Auger transition of the singly charged ion to the doubly charged ground state is accompanied by the ejection of an electron (Auger-elecron) with a kinetic energy $\varepsilon_a^{(0)} = E^{(i)} - E^{(a)} \sim 804.65$ eV and a Lorentzian line profile. In the present case we have chosen the photon energy to match the $Ne^{+2}(1s^{-1} - 3p)$ transition energy. Around this energy there is a manifold of excited states which we denote collectively as $|a'\rangle$. We show in table 1 those states which lie within a 1 eV band around the excitation photon energy. While the Auger state $|i\rangle$ decays with a lifetime of about $\Gamma_{ia}^{-1} \sim 2.44$ fs, the field, through a Rabi-type transition, creates a coherent superposition of the ionic ground state $|a\rangle$ and all accessible excited states $|a'\rangle$. This Rabi-oscillation of the K-shell electron between the bound states of the Ne^{+2} ion will induce an ac-Stark splitting manifested in the kinetic energy of the ejected Auger-electron. We should note that no post-collision interaction with the photo-electron is taken into account, as the energy of the photoelectron is too large for such an effect to contribute in the Auger's electron spectrum (and vice-versa). To complete the picture, the excited states $|a'\rangle$ decay either through an additional Auger process ($\Gamma_{a'}$) or through further ionization by absorbing one more photon ($\gamma_{a'}$). Finally, direct creation of a double core-hole Ne^{+2} of the neutral, through photoabsorption, is not considered since the double K-shell ionization energy is 1863 eV [17].

We discuss below the manner in which the AES is modified due to the Rabi-coupling of the $Ne^{+2}(1s^{-1} - 3p)$ states and study it's behaviour in a quantitative manner. To facilitate the interpretation of the results, we note at this point that for a modification of the Auger line to appear, many Rabi-oscillations should occur within the relevant Auger lifetime. Equivalently, in the energy domain, it is required that the energy separation of the Auger-line splitting (roughly equal to Rabi coupling strength) should be larger than the Auger decay width or the x-ray bandwidth, whichever is larger. Of course the detailed properties of the system and the field will matter as well, however the rule of thumb, as expressed above will be in general true.

The structure of the paper is as follows. In section II we present the theoretical formulation and develop the decription of the processes in terms of a time-dependent density matrix system of equations. In section III we show some of the results of our present study in the case of a single-mode coherent field. In the final section (Sec. IV) we summarize our findings and discuss, very briefly, two aspects of the problem that are necessary to put the description of the problem closer to the actual experimental conditions, namely the fluctuations present in a FEL field and the field's spatial dependance.

$\|a'\rangle$	$E_{a'}$ (eV)	$Ne^{+2}(1s^12s^2)$	$gf_{aa'}(\times 10^{-2})$
1	907.75	$(2p^4,^1D)^2D(3p^1)^1P_1$	2.3338
2	907.90	$(2p^4,^3P)^2P(3p^1)^3P_1$	0.20991
3	908.06	$(2p^4,^1D)^2D(3p^1)^1F_3$	8.1881
4	908.48	$(2p^4,^3P)^2P(3p^1)^3D_3$	0.13141
5	908.51	$(2p^4,^1D)^2D(3p^1)^3D_2$	0.23322
6	908.49	$(2p^4,^3P)^2P(3p^1)^1D_2$	4.4888
7	908.78	$(2p^4,^1D)^2D(3p^1)^1D_2$	1.2714

Table I. The above table lists the transitions from the $|a\rangle = Ne^{+2}(^1D_2)$ ground state to its excited states $Ne^{+2}(1s^{-1} - 3p)$ around the photon frequency $\omega = 908$ eV. The fourth column shows the corresponding oscillator strengths. The data are calculated using the Cowan suites of codes [20].

THEORETICAL FORMULATION OF THE DENSITY MATRIX EQUATIONS

The density operator of the system is obtained in the basis of $|G\rangle, |I\rangle, |A\rangle, |A'\rangle, |R\rangle, |F_i\rangle, i = 1, 2$ states. The state $|G\rangle$, with energy $E^{(g)}$, represents the neon ground state. The state $|I\rangle = |i; \varepsilon_i\rangle$, with energy $E_i = E^{(i)} + \varepsilon_i$, represents the K-shell hole Ne^+ (state $|i\rangle$ with energy $E^{(i)}$) and the photo-ejected electron $|\varepsilon_i\rangle$ having kinetic energy ε_i. The state $|A\rangle = |a; \varepsilon_a, \varepsilon_{ia}\rangle$, with energy $E_a = E^{(a)} + \varepsilon_a + \varepsilon_{ia}$, represents the Ne^{+2} ion in its ground state (state $|a\rangle$ with energy $E^{(a)}$) with an ejected Auger-electron of kinetic energy ε_a and the photoelectron having now kinetic energy ε_{ia}. Similarly, the state $|A'\rangle = |a'; \varepsilon_{a'}, \varepsilon_{ia'}\rangle$, with energy $E_{a'} = E^{(a')} + \varepsilon_{a'} + \varepsilon_{ia'}$, represents the excited state of Ne^{+2} (state $|a'\rangle$ with energy $E^{(a')}$) with the Auger electron having kinetic energy $\varepsilon_{a'}$ and the photoelectron having now kinetic energy $\varepsilon_{ia'}$. It should be noted that in the definition of the photoelectron and Auger-electron states the appropriate angular momentum quantum numbers, as they result from electric dipole and Auger transition rules, are included. In addition, we also take into account the possibility of the involvement of further decay modes. In the present case, the K-shell hole Ne^+ $|i\rangle$ can decay through fluorescence to $Ne^+(1s^22s^22p^5)$, denoted here as $|R\rangle$. Moreover, the excited states $|A'\rangle$ may further decay either through an Auger transition to $Ne^{+3}(1s^22s^22p^3)$ denoted as $|F_1\rangle$ or through further photoionization to hollow K-shell $Ne^{+3}(1s^12s^22p^4)$, denoted as $|F_2\rangle$. The equations of motion for the density matrix elements are obtained from the Liouville equation $i\dot{\hat{\rho}}(t) = [H(t), \rho(t)]$ with $\hat{H}(t) = \hat{H}^0 + \hat{V} + \hat{D}(t)$, $\hat{H}^0$ being the field-free Hamiltonian of neon, $\hat{V}$ the electron-electron interaction operator and $\hat{D}(t)$ the x-ray field-atomic dipole interaction

operator. Inserting the above states into the Liouville equation we obtain:

$$\begin{aligned}
\dot{\rho}_{GG}(t) &= 2Im \sum\!\!\!\!\!\!\int_I D_{GI}\rho_{IG}, \\
\dot{\rho}_{II}(t) &= 2Im\left[D_{IG}\rho_{GI}\right] + 2Im \sum\!\!\!\!\!\!\int_A V_{IA}\rho_{AI} \\
&\quad + 2Im \sum\!\!\!\!\!\!\int_R D_{IR}\rho_{RI} \\
\dot{\rho}_{AA}(t) &= 2Im\left[V_{AI}\rho_{IA}\right] + 2Im\left[D_{AA'}\rho_{A'A}\right] \\
\dot{\rho}_{A'A'}(t) &= -2Im\left[D_{AA'}\rho_{A'A}\right] + 2Im \sum\!\!\!\!\!\!\int_{F_1} V_{A'F_1}\rho_{F_1A'} \\
&\quad + 2Im \sum\!\!\!\!\!\!\int_{F_2} D_{A'F_2}\rho_{F_2A'} \\
i\dot{\rho}_{AA'}(t) &= E_{AA'}\rho_{AA'} + D_{AA'}(\rho_{A'A'} - \rho_{AA}) + V_{AI}\rho_{IA'} \\
&\quad - \sum\!\!\!\!\!\!\int_{F_1} \rho_{AF_1}V_{F_1A'} - \sum\!\!\!\!\!\!\int_{F_2} \rho_{AF_2}D_{F_2A'} \\
i\dot{\rho}_{GI}(t) &= ... \\
&\quad ... \; ... \; ...
\end{aligned}$$

In the above expressions $\rho_{KL}, K, L = G, I, A, A', R, F_1, F_2$ are the density matrix elements of the involved states while D_{KL} and V_{KL} represent electric dipole and Auger (intra-atomic) transitions between the states K, L, respectively. More specifically, the quantities $D_{GI}, V_{IA}, D_{IR}, D_{AA'}, V_{A'F_1}, D_{A'F_2}$ represent multielectron electric dipole (D) and Auger (V) transition matrix elements. Within the present context we do not take into account any post-collision effects between the photo- and Auger-electrons as their contribution are expected to be negligible for the considered kinetic energies. This assumption allows for a simplification of the transition matrix elements as for example for $V_{IA} = \langle i, \varepsilon_i|\hat{V}|a, \varepsilon_a, \varepsilon_{ia}\rangle$ which reduces to $V_{IA} = \langle i|\hat{V}|a\rangle\langle\varepsilon_{ia}|\varepsilon_i\rangle = V_{ia}\delta(\varepsilon_{ia} - \varepsilon_i)$. Along the same lines the dipole transition $D_{AA'} = \langle a, \varepsilon_a, \varepsilon_{ia}|\hat{D}|a', \varepsilon'_a, \varepsilon_{ia'}\rangle$, is approximated as $D_{AA'} = \langle a|\hat{D}|a'\rangle\langle\varepsilon_a|\varepsilon_{a'}\rangle\langle\varepsilon_{ia}|\varepsilon_{ia'}\rangle = d_{aa'}\delta(\varepsilon_a - \varepsilon_{a'})\delta(\varepsilon_{ia} - \varepsilon_{ia'})$. A detailed discussion of the dimensional reduction of these special kind of continuum-continuum matrix elements can be found in the appendix of Ref. [15]. The summations involved here imply integration over the appropriate continua. As the total number of independent equations is 28, we do not present the explicit expressions for the evolution of the remaining density matrix elements as they are not essential at this stage.

The density matrix equations, are a system of coupled integro-differential equations which are not amenable to an easy solution even by numerical means as it includes integration over multidimensional continua. It is thus our purpose here to transform the above system of equations into a more tractable form. To this end, we adiabatically eliminate the density matrix elements which are involved in the integrations over the respective continua of the states. The procedure for adiabatically eliminating these continua is a standard technique applied to describe the influence of a system with infinite degrees of freedom on to a system with a small number of degrees and appears in many different contexts (see e.g. [18]). Here, the reduced system is the one described by $|G\rangle, |I\rangle, |A\rangle$ and $|A'\rangle$ while $|R\rangle, |F_i\rangle, i = 1, 2$ represent the dissipative environment. Within the present context of atomic continua, some of the details can also be found in [19]. To proceed further, the radiation field is expressed as $\mathbf{E}(t) = \hat{e}(\mathcal{E}(t)e^{i\omega t} + \mathcal{E}^{\star}(t)e^{-i\omega t})/2$ with $\hat{e}$ its polarization vector and we transform to slowly varying variables by defining $\sigma_{kl} = \rho_{KL}e^{-in\omega t}, n = 0, \pm1, \pm2, \pm3$, where n is chosen so that $n\omega$ has the closest possible value to $E_K - E_L$. With the latter transformation we remove from the coherences the fast oscillation part of their evolution due to the frequency of the field (this is justified since for a frequency of 1 keV the field period is of the order of 4 as and all other time scales set by photoionization and Auger widths are of the order of 1 fs $\sim$ 1000 as). Given that the radiation is in the form of a pulse we have kept the slowly varying envelope $\mathcal{E}(t)$ which in addition may describe the stochastic properties of the field under consideration. This is however a problem which requires special care and postpone its discussion for now. In the present case, we assume a fully coherent single-mode, Fourier transform-limited, field. Then, by employing the rotating wave approximation (RWA) and keeping only the terms proportional to the first-order of the electric field, after tedious but straightforward manipulation we end up to the following set of equations for the reduced density matrix elements

$$\dot{\sigma}_{gg}(t) = -\gamma_g \sigma_{gg}, \tag{1a}$$
$$\dot{\sigma}_{ii}(\varepsilon_i, t) = -\Gamma_i \sigma_{ii} + Im\left[\Omega^{\star}_{ig}\sigma_{gi}\right], \tag{1b}$$
$$\dot{\sigma}_{aa}(\varepsilon_i, \varepsilon_a, t) = -Im\left[\Omega^{\star}_{a'a}\sigma_{aa'}\right] + 2Im\left[V_{ai}\sigma_{ia}\right], \tag{1c}$$
$$\dot{\sigma}_{a'a'}(\varepsilon_i, \varepsilon_a, t) = -\bar{\gamma}_{a'}\sigma_{a'a'} + Im\left[\Omega^{\star}_{a'a}\sigma_{aa'}\right], \tag{1d}$$
$$i\dot{\sigma}_{aa'}(\varepsilon_i, \varepsilon_a, t) = (E_{aa'} + \omega - i\frac{\bar{\gamma}_{a'}}{2})\sigma_{aa'} + \frac{\Omega_{aa'}}{2}(\sigma_{a'a'} - \sigma_{aa}) + V_{ai}\sigma_{ia'}, \tag{1e}$$
$$i\dot{\sigma}_{gi}(\varepsilon_i, t) = (E_{gi} + \omega - i\frac{\gamma_g + \Gamma_i}{2})\sigma_{gi} - \frac{1}{2}\Omega_{gi}\sigma_{gg}, \tag{1f}$$
$$i\dot{\sigma}_{ia}(\varepsilon_i, \varepsilon_a, t) = (E_{ia} - i\frac{\Gamma_i}{2})\sigma_{ia} + \frac{1}{2}\Omega^{*}_{ig}\sigma_{ga} - \frac{1}{2}\Omega^{*}_{a'a}\sigma_{ia'} - V_{ia}\sigma_{ii}, \tag{1g}$$
$$i\dot{\sigma}_{ia'}(\varepsilon_i, \varepsilon_a, t) = (E_{ia'} + \omega - i\frac{\Gamma_i + \bar{\gamma}_{a'}}{2})\sigma_{ia'} + \frac{1}{2}\Omega^{*}_{ig}\sigma_{ga'} - \frac{1}{2}\Omega_{aa'}\sigma_{ia}, \tag{1h}$$
$$i\dot{\sigma}_{ga}(\varepsilon_i, \varepsilon_a, t) = (E_{ga} + \omega - i\frac{\gamma_g}{2})\sigma_{ga} - \frac{1}{2}\Omega^{*}_{a'a}\sigma_{ga'} - V_{ia}\sigma_{gi}, \tag{1i}$$
$$i\dot{\sigma}_{ga'}(\varepsilon_i, \varepsilon_a, t) = (E_{ga'} + 2\omega - i\frac{\gamma_g + \bar{\gamma}_{a'}}{2})\sigma_{ga'} - \frac{1}{2}\Omega_{aa'}\sigma_{ga}, \tag{1j}$$

where $\Omega_{gi}(\varepsilon_i, t) = \langle g|\hat{D}|i, \varepsilon_i\rangle\mathcal{E}(t)$ and $\Omega_{aa'}(t) = d_{aa'}\mathcal{E}(t)$. With $\gamma_g(t) = 2\pi\int d\varepsilon_i|\Omega_{gi}(\varepsilon_i, t)|^2$ we denote the photoionization width of the neon ground states relative to the Ne^+ K-shell hole state $|i\rangle$, while $\bar{\gamma}_{a'} = \Gamma_{a'} + \gamma_{a'}(t)$ is the sum of the Auger decay width to states $|F_1\rangle$ ($\Gamma_{a'}$) and the photoionization width to states $|F_2\rangle$ ($\gamma_{a'}$) of the excited states $|a'\rangle$. In addition, $\Gamma_i = \Gamma_{ia} + \gamma_r$, is the sum of the decay width of the ionic state $|i\rangle$ through Auger decay to states $|a\rangle$ and through fluorescence to states $|R\rangle$. The quantity V_{ia} represents the strength of the Auger transition of the hole state $|i\rangle$ to the particular ionic ground state $|a\rangle$. Therefore, the quantity Γ_{ia} is expressed as $\Gamma_{ia} = 2\pi|V_{ia}|^2$. Finally the energy differences in the above equations now include all the shifts associated with the Auger and dipole couplings of the relevant states with continuum states $E_{kl} \equiv E_k + S_k - (E_l + S_l), k, l = g, i, a'$ with $S_i = S_{ia} + S_{ir}$ and $S_{a'} = S_{a'f_1} + S_{a'f_2}$. The exact definition of the shifts and widths are as below:

$$S_g - i\frac{\gamma_g}{2} = \lim_{\eta\to 0}\int dE_I \frac{|D_{GI}|^2}{E_G + \omega - E_I + i\eta},$$
$$S_{ia} - i\frac{\Gamma_{ia}}{2} = \lim_{\eta\to 0}\int dE_A \frac{|V_{IA}|^2}{E_I - E_A + i\eta},$$
$$S_{ir} - i\frac{\Gamma_{ir}}{2} = \lim_{\eta\to 0}\int dE_R \frac{|D_{IR}|^2}{E_I - E_R + i\eta},$$
$$S_{a'f_1} - i\frac{\Gamma_{a'}}{2} = \lim_{\eta\to 0}\int dE_{F_1} \frac{|V_{A'F_1}|^2}{E_{A'} - E_{F_1} + i\eta},$$
$$S_{a'f_2} - i\frac{\gamma_{a'}}{2} = \lim_{\eta\to 0}\int dE_{F_2} \frac{|D_{A'F_2}|^2}{E_{A'} + \omega - E_{F_2} + i\eta},$$

where use of the well-known formula $\lim_{\eta\to 0} 1/(x + i\eta) = \mathcal{P}(1/x) - i\pi\delta(x)$ must be made to split up the integrals into their real and imaginary parts.

At this stage, a working set of equations are established and their numerical solution is feasible, provided that all the dynamical parameters of the problem have been calculated before-hand. The approximations leading to this set of equations require careful examination of the appropriate range of radiation intensities. One approximation is to assume that the relevant continua are smooth around the energies of the dressed bound states within an energy range comparable with the Rabi-coupling matrix element. This requires that transitions close to ionization thresholds should not be considered. In addition, in the derivation procedure, we have ignored terms proportional to the second order of the field, such that $\Omega_{aa'} < 1$. The latter approximation, given the matrix element $d_{aa'} \sim 0.06$ a.u., will restrict the range of the intensities where the working equations are applicable below to 4×10^{18} W/cm^2.

The system of equations that have been derived must, simultaneously, be numerically integrated for all different photo-electron and Auger-electron kinetic energies, so as to provide the populations for $\sigma_{ii}(\varepsilon_i), \sigma_{aa}(\varepsilon_a, \varepsilon_i), \sigma_{a'a'}(\varepsilon_a, \varepsilon_i)$ at infinite times. Since in our case we are only interested in the Auger-kinetic energy spectrum and ionization yields regardless of the state of the photoelectron, we must integrate the final populations over the photo-electron kinetic energies and determine the following probabilities $\sigma_{ii} = \int d\varepsilon_i\sigma_{aa}(\varepsilon_i), \sigma_{aa}(\varepsilon_a) = \int d\varepsilon_i\sigma_{aa}(\varepsilon_a, \varepsilon_i), \sigma_{a'a'}(\varepsilon_a) = \int d\varepsilon_i\sigma_{a'a'}(\varepsilon_a, \varepsilon_i)$. An alternative and more economical way of obtaining the same results is to derive a coarse-grained version of the present equations for these reduced, averaged over the photoelectron energies, density matrix elements. In addition, the reduced set of the density matrix equations is amenable to further manipulation as it allows for the derivation of analytical expressions for long pulses or their averaging for stochastic pulses. Thus, the new reduced set of equations, is obtained by first setting all the derivatives of the coherences equal to zero [except $\dot{\sigma}_{aa'}(\varepsilon_a, \varepsilon_i, t)$] and then integrating

over the photoelectron energy ε_i. To demonstrate the reasoning of setting the derivatives of the coherences to zero, we work out the evolution equation of $\sigma_{gi}(\epsilon_i, t)$ coherence [Eq. (1f)]. We integrate Eq. (1f) in an interval $t, t+\tau$ with $\tau << \Omega_{aa'}^{-1}, \gamma_g^{-1}, \Gamma_i^{-1}$ and we obtain:

$$i[\sigma_{gi}(\varepsilon_i, t+\tau) - \sigma_{gi}(\varepsilon_i, t)] = (E_{gi}(\tau) + \omega - i\frac{\gamma_g(\tau)+\Gamma_i}{2}) \int_t^{t+\tau} dt' \sigma_{gi}(\varepsilon_i, t') - \frac{\Omega_{gi}(\varepsilon_i, \tau)}{2} \int_t^{t+\tau} dt' \sigma_{gg}(t').$$

The ionization width $\gamma_g(\tau)$, the dipole $\Omega_{gi}(\varepsilon_i, \tau)$ and the $S_g(\tau), S_i(\tau)$ ac-Stark shifts that are included in the definition of $E_{gi}(\tau)$ were removed from the integral as their value doesn't change much between t and $t+\tau$ as a result of the slowly varying trasformation of the variables. Since it will always be $|\sigma_{gi}(\varepsilon_i, t)| << \sigma_{gg}(t)$, we can neglect the left hand side and obtain the 'coarse grained' time average of $\sigma_{gi}(\varepsilon_i, t)$ as:

$$\bar{\sigma}_{gi}(\varepsilon_i, \tau) = \frac{\Omega_{gi}(\varepsilon_i, \tau)/2}{E_{gi}(\tau) + \omega - i(\gamma_g(\tau)+\Gamma_i)/2} \bar{\sigma}_{gg}(\tau), \quad (2)$$

where $\bar{\sigma}_{gi}(\varepsilon_i, \tau) \equiv \int_t^{t+\tau} dt' \sigma_{gi}(\varepsilon_i, t')/\tau$ and $\bar{\sigma}_{gg}(\tau) \equiv \int_t^{t+\tau} dt' \sigma_{gg}(t')/\tau$. Thus, by setting the derivative of the coherence to zero, effectively, leads to a coarse-grained value for the coherence which follows adiabatically the ground state population. At this stage, integrating Eq. (1b) over time (in an interval $[t, t+\tau]$) and the photoelectron energy ε_i we obtain:

$$\begin{aligned} \dot{\sigma}_{ii}(\tau) &= -\Gamma_i \sigma_{ii}(\tau) + Im \int d\varepsilon_i \frac{|\Omega_{gi}(\varepsilon_i, \tau)|^2/2}{E_{gi}(\tau) + \omega - i(\gamma_g(\tau)+\Gamma_i)/2} \sigma_{gg}(\tau) \\ &= -\Gamma_i \sigma_{ii}(\tau) + \gamma_g(\tau) \sigma_{gg}(\tau), \end{aligned} \quad (3)$$

where $\sigma_{ii}(\tau) = \int d\varepsilon_i \bar{\sigma}_{ii}(\varepsilon_i, \tau)$ and $\bar{\sigma}_{ii(\varepsilon_i,\tau)} = \int_t^{t+\tau} dt' \sigma_{ii}(\varepsilon_i, t')$. To evaluate the integral we have assumed that $\Omega_{gi}(\varepsilon_i, \tau)$ is smooth over an energy range equal to the radiation's bandwidth (far from resonance structures in the continuum or ionization thresholds). Then by expressing E_{gi} as $E_{gi}(\tau) = E^{(g)} + S_g(\tau) - E^{(i)} - S_i(\tau) - \varepsilon_i$ we have $Im \int d\varepsilon_i |\Omega_{gi}(\varepsilon_i, \tau)|^2/(E_{gi}(\tau) + \omega - i(\gamma_g(\tau)+\Gamma_i)/2) \sim \pi |\Omega_{gi}(\varepsilon_i = E^{(i)} + S_i - E^{(g)} - S_g, \tau)|^2 = 2\gamma_g(\tau)$.

As the derivation is quite long and detailed for the remaining coherences, we give here only the final result for the reduced (coarse-grained) set of density matrix equations. These reduced equations are obtained working along similar lines as for the derivation of Eq. (3). In this derivation, we ingore the photoionization of the excited $|a'\rangle$, ($\gamma_{a'} = 0$) as for the photon energies and the intensities considered is expected to be much less than the Auger decay transition, represented by $\Gamma_{a'}$. Therefore, after setting all the derivatives of the coherences equal to zero [Eqns. (1f), (1g), (1h), (1i), (1j)], we solve for the coherences and substitute their values into Eqns (1c), (1d) and (1e). Then we integrate our equations over the photoelectron's kinetic energy and obtain the coarse-grained (also changing $\tau \to t$) set of density matrix equations,

$$\dot{\sigma}_{gg}(t) = -\gamma_g \sigma_{gg}, \quad (4a)$$

$$\dot{\sigma}_{ii}(t) = -\Gamma_i \sigma_{ii} + \gamma_g \sigma_{gg}, \quad (4b)$$

$$\dot{\sigma}_{aa}(\varepsilon_a, t) = -Im\left[\Omega_{a'}^{\star} \sigma_{aa'}\right] + Im\left[(\Delta_a + \delta_{a'} - i\frac{\Gamma_i + \Gamma_{a'}}{2})(\Omega_{a'}^{+} - \Omega_{a'}^{-})\right] \sigma_{ii}, \quad (4c)$$

$$\dot{\sigma}_{a'a'}(\varepsilon_a, t) = -\Gamma_{a'} \sigma_{a'a'} + Im\left[\Omega_{a'}^{\star} \sigma_{aa'}\right], \quad (4d)$$

$$i\dot{\sigma}_{aa'}(\varepsilon_a, t) = (\delta_{a'} - i\frac{\Gamma_{a'}}{2})\sigma_{aa'} - \frac{\Omega_{a'}}{2}(\sigma_{a'a'} - \sigma_{aa}) + \frac{\Omega_{a'}}{4}(\Omega_{a'}^{+} - \Omega_{a'}^{-})\sigma_{ii}. \quad (4e)$$

The dynamics of the process are governed by the ionization width of the neutral target $\gamma_g(t)$, the core Rabi-

coupling $\Omega_{a'}(t)$ the intra-atomic decay rates $\Gamma_i, \Gamma_{a'}$, the Auger-field induced couplings $\Omega^{\pm}_{a'}(t)$ and the Auger $\Delta_a(t) = E_i - (E_a + \varepsilon_a)$ and field $\delta_{a'}(t) = (E_a + \omega) - E_{a'}$ detunings. Note that for notational simplicity we denote the core Rabi coupling as $\Omega_{a'} = \Omega_{aa'} = \Omega_{a'a}$. We have defined $\Omega^{\pm}_{a'}(t) = 2|V_{ia}|^2/(\Delta^{\pm}_{a'}\bar{\Omega}_{a'})$ with $\Delta^{\pm}_{a'}(t) = \epsilon_a - \epsilon^{\pm}_a + i\gamma^{\pm}_a(t)/2$, $\epsilon^{\pm}_a(t) = \epsilon^{(0)}_a + [\delta_{a'} \mp \bar{\Omega}^{(r)}_{a'}(t)]/2$ and $\gamma^{\pm}_a(t) = \Gamma_i + [\Gamma_{a'} \pm \bar{\Omega}^{(i)}_{a'}(t)]/2$. The real quantities $\bar{\Omega}^{(r)}_{a'}$ and $\bar{\Omega}^{(i)}_{a'}$ are defined in terms of the generalized Rabi frequency:

$$\bar{\Omega}_{a'}(t) = \bar{\Omega}^{(r)}_{a'} + i\frac{\bar{\Omega}^{(i)}_{a'}}{2} = \sqrt{(\delta_{a'} - i\frac{\Gamma_{a'}}{2})^2 + 4|\Omega_{a'}|^2}. \quad (5)$$

The AES, at detection time, is obtained by adding the contributions from the ground $|a\rangle$ and excited $|a'\rangle$ states of the doubly-ionized neon: $S(\varepsilon_a) = \sum_{j=a,a'} \int_{-\infty}^{+\infty} dt' \dot{\sigma}_{jj}(\varepsilon_a, t')$. The populations of the states $|a\rangle$ and $|a'\rangle$ are obtained as $p_{jj}(t) = \int_{-\infty}^{+\infty} dt \int d\varepsilon_i \dot{\sigma}_{jj}(\varepsilon_a, t')$, $j = a, a'$. Although we numerically integrate the above system of density matrix equations Eqns (4) the Auger spectra can also be cast in analytical form to a very good approximation. For example, for a non-decaying excited states ($\Gamma_{a'} = 0$) the generalized Rabi frequency becomes a purely real quantity $\bar{\Omega}_{a'} = \sqrt{\delta^2_{a'} + 4|\Omega_{a'}|^2}$ while the AES become independent on the coherence evolution $\sigma_{aa'}$. The analytical approximation consists of considering a pulse of constant amplitude $\mathcal{E}(t)$ which turns the coarse-grained system to a system of ordinary differential equations with constant coefficients. Then the Rabi frequency, ac-Stark level shifts and the ionization widths become independent on time and in the expression for the AES only the population of $|i\rangle$ is time-dependent:

$$\begin{aligned} S(\varepsilon_a) &= \int_{-\infty}^{+\infty} dt \left[\dot{\sigma}_{aa}(\varepsilon_a, t) + \dot{\sigma}_{a'a'}(\varepsilon_a, t)\right] \\ &= Im[(\Delta_a + \delta_{a'} - i\frac{\Gamma_i}{2})(\Omega^{+}_{a'} - \Omega^{-}_{a'})] \int_{-\infty}^{+\infty} dt \sigma_{ii}(t). \end{aligned}$$

Solving the Eqns (4a) and (4b) for $\sigma_{ii}(t)$ we find that $\int_{-\infty}^{+\infty} dt \sigma_{ii}(t) = 1/\Gamma_i$ and after some algebra we end up to the following analytical expression for the AES:

$$S(\varepsilon_a) = \frac{\Gamma_{ia}}{4\pi}\left[\frac{1 - \delta_{a'}/\bar{\Omega}_{a'}}{(\varepsilon_a - \varepsilon^{(0)}_a - \frac{\delta_{a'} - \bar{\Omega}_{a'}}{2})^2 + \frac{\Gamma_i^2}{4}} + \frac{1 + \delta_{a'}/\bar{\Omega}_{a'}}{(\varepsilon_a - \varepsilon^{(0)}_a - \frac{\delta_{a'} + \bar{\Omega}_{a'}}{2})^2 + \frac{\Gamma_i^2}{4}}\right]. \quad (6)$$

We should note here, that the predictions of the analytical expression differ from the numerical solution in that it doesn't include the transient effects of the physical process which are expected to occur at times of the order of $1/\Gamma_i$:

RESULTS

In Fig. 2 we show the effect of the field strength in the Auger spectra for $\omega = 908.06$ eV and assume a pulse envelope $\mathcal{E}(t) = \sin^2(\pi t/T)$, with T being the total pulse duration equal to about 20 times the Auger life time ~ 48.8 fs (FWHM = 24.4 fs). More specifically in all the following calculations the field included 10754 cycles. The ionization width of the neutral is given by $\gamma_g(t) = 4.375 \times 10^{-4}\mathcal{E}^2(t)$ a.u.. In the calculation we only include the $|a'\rangle = |\mathrm{Ne}^{+2}(1s^{-1} - 3p),\ ^1\mathrm{F}\ \rangle$ excited state [state 3 of table 1] and assume its decay width to be zero ($\Gamma_{a'} = 0$). For this, on-resonance process ($\delta_{a'} = 0$), the Rabi interaction energy is found to be $\Omega_{a'} = 0.061\mathcal{E}(t)$ a.u.. According to Eq. (6), for peak intensities of $I_0 = 1.0\times10^{15}, 1.0\times10^{16}, 3.51\times10^{16}, 1.0\times10^{17}$ and 3.51×10^{17} W/cm^2 peak separations (of equal height) of about $0.28, 0.88, 1.66, 2.79$ and 5.25 eV, respectively, should be expected for the AES. Particularly, for the lowest intensity of $I_0 = 1.0 \times 10^{15}$ the peak separation is comparable to the Auger decay width (0.27 eV), thus the separation is hardly seen. The latter values coincide with the full numerical solutions, shown in Fig 2. In general, according to the above formula, for on-resonance conditions and long pulses (compared to $1/\Gamma_i$) a change of the splitting by a factor around 3.2 should be expected, for a change of the peak intensity by one order of magnitude. For off-resonance conditions we have two unequal peaks with energy separation again determined from the generalized Rabi-frequency $\bar{\Omega}_{a'}$ and relative height determined from the field detuning $\Delta_{a'}$.

Next we turn to the case where the decay channels of the excited core states $|a'\rangle$ are present. We have found that for the intensities and photon energy considered, further photoionization of $|a'\rangle$ is a much weaker channel compared with a RAS transition to Ne^{+3} [20, 21]. We take the RAS width to be a large fraction of $\mathrm{Ne}^{+3}(1s2p^22p^4) \rightarrow \mathrm{Ne}^{+3}(1s^22p^22p^3)$ decay width and assume $\Gamma_{a'} = 0.156$ eV [21]. In this case the life time of these excited ionic states $|a'\rangle$ is about 4.12 fs, comparable to the Auger decay life time of interest here (~ 2.45 fs) but still much shorter than the pulse duration. Given that the Rabi coupling saturates the $\mathrm{Ne}^{+2}(1s^{-1} - 3p)$ transition very quickly (in the sense that their populations are almost equalized) it can be expected that a

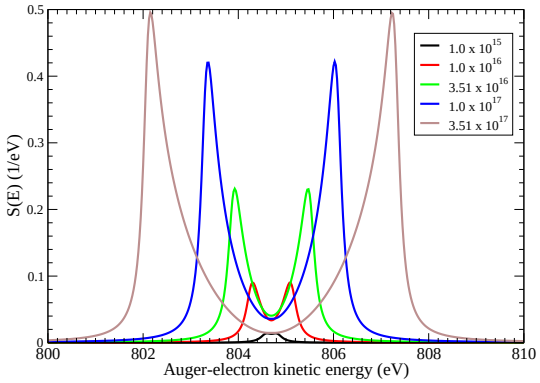

Figure 2. (Color online) Variation in the AES as the peak intensity of the pulse increases. The field has total duration about 48.8 fs (FWHM = 24.4 fs) and the photon frequency chosen equal to 908.06 eV, while $\Gamma_{a'} = 0$. The inset label give the

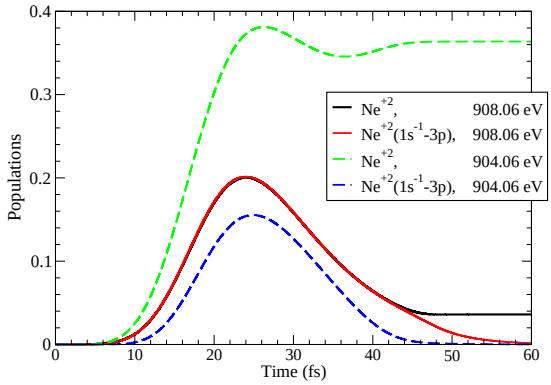

Figure 4. (Color online) Populations of the Ne^{+2} and $Ne^{+2}(1s^{-1} - 3p)$ states as a function of time peak intensity $I_0 = 5.0 \times 10^{17}$ W/cm^2. All other parameters as in Fig. 3.

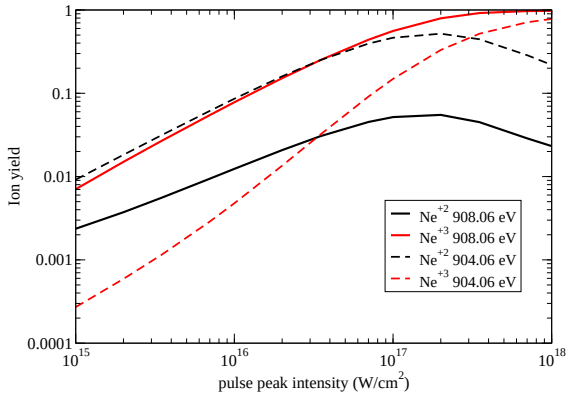

Figure 3. (Color online). Ionization yields versus the peak intensity of the x-ray field. Field parameters as in Fig. 2 and $\Gamma_{a'} = 0.156$ eV. Solid curves refer to $\omega = 908.06$ eV while the dashed ones to $\omega = 904.06$ eV.

large portion of the population will very quickly decay to the Ne^{+3} ion. This behaviour is shown in Fig. 3 where the final populations in Ne^{+2} and Ne^{+3} are plotted as a function of the peak intensity of the applied x-ray field. Thus for on-resonance cases (solid lines) we see that the majority of the population goes into Ne^{+3} ion for all intensities considered. On the other hand, if we choose to detune the FEL to a photon energy of 904.06 eV (dashed lines), efficient population of the excited ionic state $|a'\rangle$ is prohibited. This also causes an effective increase in the magnitude of the generalized Rabi frequency according to Eq. (5). In that case the situation changes dramatically. The relative population ratio is reversed for low intensity fields ($< 10^{17}$ W/cm^2), with the Ne^{+2} dominating up to higher intensities where the ratio starts to decline in favor of the Ne^{+3} yield. Thus, it appears that a careful combination of the intensity and the photon energy of the field can control the relative populations of the triply and doubly ionic species of neon. It is worth to note here that for the present long pulses and for relatively strong fields ($> 3.5 \times 10^{16}$ W/cm^2), the depletion of the neutral neon might be significant. For example, for $I_0 = 3.5 \times 10^{16}$ W/cm^2 the remaining neutral neon is 0.718 while for ten times stronger field $I_0 = 3.5 \times 10^{17}$ W/cm^2 decreases to 0.036. Furthermore, it should also be noted that ionic species higher than triply and doubly ionized neon are not expected to contribute significantly as two- or multi- photon absorption is an unlikely ionization channel, given their ionization potentials and the large photon energy. Finally, a small fraction of Ne^{+1} is produced through the fluorescence of the metastable K-shell hole Ne^{+1} ion.

In Fig. 4 we show the populations of the Ne^{+2} and $Ne^{+2}(1s^{-1} - 3p)$ excited states as a function of time for a field of peak intensity 1.0×10^{17} W/cm^2. We have considered two different frequencies as in the case of Fig. 3, which represent the on-resonance (908.06, eV-solid lines) and off-resonance (904.06, dashed-lines) conditions. From this figure, we can see that the populations of Ne^{+2} and $Ne^{+2}(1s^{-1} - 3p)$ are quickly (almost) equalized, thus allowing for the efficient production of the Ne^{+3} ion through the Auger decay of the excited $Ne^{+2}(1s^{-1} - 3p)$ state with the ejection of one more electron ($\Gamma_{a'} = 0.156$ eV). With off-resonance conditions we see that the same populations evolve differently with the amount of Ne^{+3} that is produced being significantly smaller than the Ne^{+2} yield for a broad range of intensities. Of course, even in the detuned case, when the intensity becomes higher, the Rabi amplitude will increase accordingly and again the quick transfer from the ground Ne^{+2} to the excited $Ne^{+2}(1s^{-1} - 3p)$ state will allow the efficient production of the Ne^{+3} ion. In that case Ne^{+3} yield will surpass Ne^{+2} yield. By inspection of Fig. 3, the intensities that this overtaking of Ne^{+3} takes place are beyond $3.5 \times 10^{+17}$ W/cm^2.

CONCLUSION

We have presented a theory of the Auger kinetic spectra and ionization yields based on the time-dependent density matrix theory which encapsulates all the essential dynamical parameters of the physical processes that are involved such as photo-ionization, photo-excitation and Auger transitions. We have examined the AES and the ionic yields in the case where an inner-shell photoionization takes place followed by an Auger decay of the singly charged hole-system. We have demonstrated the emergence of ac-Stark splitting of the Auger resonance, resulting from strong Rabi-couplings. In addition, ionization yields have been calculated for a range of intensities. We show how to control the branching ratios of various ionic species by varying dynamical parameters of the system, such as Rabi coupling and detunings. The theory was applied to the case of K-shell ionization of neon with the photon frequency chosen to match the energy differences between ionic Ne^{+2} ground and excited states.

In the present study, we have put aside the issue of a field undergoing fluctuations suitable for the description of more realistic situations. A more realistic approach is to assume a field with an amplitude undergoing random fluctuations [10]. In general, the fluctuations of the field give rise to a nonzero bandwidth (beyond the Fourier bandwidth) and intensity fluctuations [22, 23]. The main differences are that the field will excite a number of (nearby) excited states (see for example the most important ones in the table 1), basically those that lie within the x-ray field bandwidth and that the width of the Auger spectrum will be effectively increased with the x-ray bandwidth. The development of the appropriate theory, capable to describe the field fluctuations, requires a detailed formulation which is beyond the purposes of the present study and it will be the subject of a future work. The essential outcome of the present work, namely the emergence of the ac-Stark splitting in the Auger spectra under the presence of strong ionic Rabi-couplings, will remain and the stochastic nature of the field will mainly affect its observability.

Finally, keeping the focus on the essence of the issue of experimental observability, we refrain from showing the influence of the volume integration in the final results, but its precise contribution needs to be evaluated when it comes to the actual experimental conditions.
